CS143: Query processing and join algorithms

Join algorithms

(R and S example slide)

- \mathbf{Q} : How to join R and S? What is the simplest algorithm? What if we have an index? Any other ideas that we can use?
 - Four join algorithms
 - * Nested-loop join
 - * Index join
 - * Sort-merge join
 - * Hash join
 - We now learn how they work

1. Nested-Loop Join:

(nested-loop-join slide)

```
For each r in R do
  For each s in S do
  if r.C = s.C then output r,s pair
```

- Q: If R has 100,000 tuples, how many times the entire S table is scanned?
- The simplest algorithm. It works, but may not be efficient.

2. Index Join:

(index-join slide)

```
For each r in R do
  X <- index-lookup(S.C, r.C)
For each s in X do
  output (r,s)</pre>
```

- Look up index to find matching tuples from S.
- Q: Benefit of index join compared to nested-loop join?

3. Sort-Merge Join:

(Sort-merge-join slide)

- Main idea: If tables have been sorted by the join attribute, we need to scan each table only once.
 - Maintain one cursor per table and move the cursor forward.
- Sort tables and join them.

(sort-merge algorithm slide)

```
(1) if R and S not sorted, sort them
(2) i <- 1; j <- 1;
   While (i <= |R|) AND (j <= |S|) do
    if R[i].C = S[j].C then outputTuples
    else if R[i].C > S[j].C then j <- j+1
    else if R[i].C < S[j].C then i <- i+1

Procedure outputTuples
   While (R[i].C = S[j].C) AND (i <= |R|) do
        k <- j;
   While (R[i].C = S[k].C) AND (k <= |S|) do
        output R[i], S[k] pair;
        k <- k + 1;
        i <- i + 1;</pre>
```

4. Hash Join:

- Main idea: If hash values are different, the tuples will never join, i.e., if $h(R.C) \neq h(S.C)$, then $R.C \neq S.C$.
- Join two tuples only if their hash values are the same.

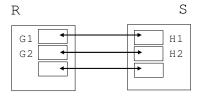

(hash-join algorithm slide)

(1) Hashing stage (bucketizing)

```
Hash R tuples into G1,...,Gk buckets Hash S tuples into H1,...,Hk buckets
```

(2) Join stage

```
For i = 1 to k do
  match tuples in Gi, Hi buckets
```

Comparison of Join Algorithms

- **Q:** Which algorithm is better?
- **Q:** What do we mean by "better"?

Cost model

- The ultimate bottom-line:
 - How long does it take for each algorithm to finish for a particular data?
- Need of cost model
 - We need a "cost model" to estimate the performance of different algorithms
- Our cost model: Total number of disk blocks that have been read/written
 - Not very realistic
 - * Ignore random, sequential IO issues, CPU cost, etc.
 - Yet simple to analyze and doable in class
 - * More sophisticated models are too complex to analyze in class
 - Good approximation given that disk IOs dominate the cost
 - * Most algorithms that we will study do mostly sequential scan
 - A better algorithm = smaller number of disk block access
 - Ignore the last IOs for result writing (the same for every algorithm)

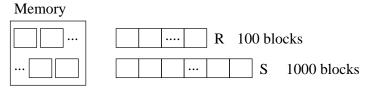

Example to use

- Two tables R, S
- |R| = 1,000 tuples, |S| = 10,000 tuples, 10 tuples/block
- $b_R = 100$ blocks, $b_S = 1{,}000$ blocks
- Memory buffer for 22 blocks

	Cost	Formula (if $b_R < b_S$)
Nested Loop		
Sort Merge		
Hash		
Index		

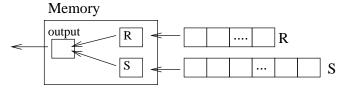

Cost of join stage of sort-merge join

- Usage of main memory blocks for join
 - 1. Available memory buffers. Disk blocks of each table

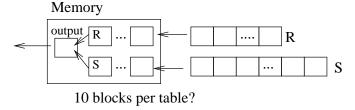

22 blocks

- 2. We need to read R table, S table and write the output.
 - Disk transfer unit is one block
 - \rightarrow At least one memory buffer block to read R, read S and write output.
 - \rightarrow Three memory blocks used for these tasks.

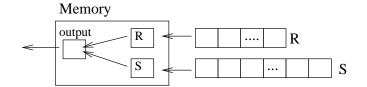

- 3. We sequentially read R and S blocks one block at a time, and join them (using the join algrothm)
- Q: How many disk IOs (block reads/writes) for R and S during join stage?
- **Q:** Under our cost metric, can we make it more efficient by allocating more buffers for reading R and S? For example,

Nested-Loop Join

(naive nested-loop join algorithm slide for reminder)

(join diagram)

- Q: How many disk blocks are read?
- **Q:** Can we do any better?

Optimization 1: Block-nested loop join

Once we read a block from R, join everything in the block in one scan of S. \rightarrow reduces the number of scans of S table

- **Q:** What is the cost?
- **Q:** Can we do any better?

Optimization 2

Read as many blocks of R and join them togeter in one scan of S \rightarrow reduces the number of scans of S table

• Q: What is the maximum # of blocks that we can read in one batch from R?

- **Q:** What is the cost?
- **Q:** What is general cost for b_R , b_S and M?
- \mathbf{Q} : What if we read S first? Would it be any different?
 - \rightarrow Use smaller table for the outer loop.

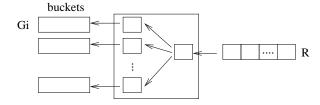

• Summary

- Always use block nested loop (not the naive algorithm)
- Read as many blocks as we can for the left table in one iteration
- Use the smaller table on the left (or outer loop)

Hash Join

(hash join slide for reminder. two stages: hashing stage and join stage)

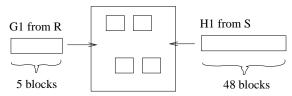

• Hashing stage: Read R (or S) table and hash them into different buckets.

- **Q:** One block for reading R, other blocks for bucketizing. How many buckets?

- **Q:** Assuming random hashing, how many blocks per bucket?
- \mathbf{Q} : During bucketizing, R table is read once and written once. How many disk IOs (read or write)?
- Repeat the same for S

• Join stage: Join H_1 with G_1

- **Q:** 5 blocks for G_1 , 48 blocks for H_1 . How should we join G_1 and H_1 ?
- **Q:** How many disk IOs?
- **Q:** Total disk IOs?
- **Q:** What if R is large and $G_1 > 20$?

Recursive partitioning

* # of bucketizing steps: $\left\lceil \log_{M-1} \left(\frac{b_R}{M-2} \right) \right\rceil$

* General hash join cost $(b_R < b_S)$:

$$2(b_R + b_S) \left\lceil \log_{M-1} \left(\frac{b_R}{M-2} \right) \right\rceil + (b_R + b_S)$$

Index join

(index-join slide for reminder)

• Q: How many disk IOs?

• Q: What should the system do to perform index join?

Index join cost:

- IO for R scanning
- IO for index look up
- IO for tuple read from S.

\bullet Example 1

- 15 blocks for index
 - * 1 root, 14 leaf
- On average, 1 matching S tuples per an R tuple.

Q: How many disk IOs? How should we use memory?

Q: Any better way?

• Example 2

- 40 blocks for index
 - * 1 root, 39 leaf
- On average, 10 matching tuples in S.

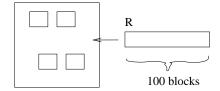

Q: How many disk IOs? How should we use memory?

- General cost: $b_R + |R| \cdot (C+J)$
 - C average index look up cost
 - J matching tuples in S for every R tuple
 - |R| tuples in R
- **Q:** How can we compute J?
 - **Example:** $R \bowtie_{R.C=S.C} S$. |S| = 10, V(C,R) = 1,000. Uniform distribution for C values. How many tuples in S with C = c?

Sort-Merge Join

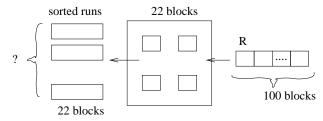

- Two stage algorithm:
 - 1. Sort stage: Sort R and S
 - 2. Merge stage: Merge sorted R and S
- # of disk IOs during merge stage: $b_R + b_S = 100 + 1,000 = 1,100$.
- Q: How many disk IOs during sort stage?

Merge sort algorithm

• Q: How many blocks can we sort in main memory?

- **Q:** Do we need to allocate one block for output?
- Q: How many sorted runs after sorting R in chunk of 22 blocks?

• **Q:** What should we do with 5 sorted-runs?

- Q: How many disk IOs?
 - **Q:** During first-stage sorting?
 - **Q:** During second-stage merging?

Repeat it for S table of 1,000 blocks. Show that now we need three stages.

- In general, the number of passes for b_R and M: $(\lceil \log_{M-1}(b_R/M) \rceil + 1)$
 - Verify it at home on your own.
 - Total # of IOs for sorting: $2 \cdot b_R(\lceil \log_{M-1}(b_R/M) \rceil + 1)$

Total sort-merge join cost

- In total: $400 + 6{,}000 + 1{,}100 = 7{,}500$
- In general: $2b_R(\lceil \log_{M-1}(b_R/M) \rceil + 1) + 2b_S(\lceil \log_{M-1}(b_S/M) \rceil + 1) + (b_R + b_S)$ IOs

Summary of join algorithms

- Nested-loop join ok for "small" relations (relative to memory size)
- Hash join usually best for equi-join
 - if relations not sorted and no index
- Merge join for sorted relations
 - Sort merge join good for non-equi-join
- Consider index join if index exists
- To pick the best, DBMS maintains statistics on data

High-level query optimization

Tables: R(A, B), S(B, C), T(C, D)

• **Q:** How can we process the following query?

- Many different ways. (Show a couple of logical query trees)

• Q: For now, focus on $R \bowtie S \bowtie T$. How many different ways to execute it?

- In general, for n way joins, $\frac{(2(n-1))!}{(n-1)!}$ ways.
 - Study why this is the case at home.
 - For n = 3, 4!/2! = 12
 - For n = 5, 8!/4! = 1680
 - For n = 10, $18!/9! = 17 \times 10^9$
- DBMS tries to pick the best based on statistics
 - In reality, picking the best is too difficult
 - * For n = 10, it is clearly impossible to examine all 17 billion plans
 - DBMS tries to avoid "obvious mistakes" using a number of heuristics to examine only the ones that are likely to be reasonable
- Read the PDF file on databse tuning and optimization
 - For 90% of the time, DBMS picks a good plan
 - To optimize the remaining 10%, companies pay big money to datbase consultants

Statistics collection commands on DBMS

- DBMS has to collect statistics on tables/indexes for optimal performance
 - Without stats, DBMS does stupid things
- DB2
 - RUNSTATS ON TABLE <userid>. AND INDEXES ALL
- Oracle
 - ANALYZE TABLE COMPUTE STATISTICS
 - ANALYZE TABLE ESTIMATE STATISTICS (cheaper than COMPUTE)
- Run the command after major update/index construction
- Does not matter for MySQL. No optimization based on actual data. Only rule-based optimizer.
